Comparing 3T and 1.5T MRI for Mapping Hippocampal Atrophy in the Alzheimer's Disease Neuroimaging Initiative

N. Chow, K.S. Hwang, S. Hurtz, A.E. Green, J.H. Somme, P.M. Thompson, D.A. Elashoff, C.R. Jack, M. Weiner, and L.G. Apostolova, for the Alzheimer's Disease Neuroimaging Initiative

ABSTRACT

BACKGROUND AND PURPOSE: Prior MR imaging studies, primarily at 1.5T, established hippocampal atrophy as a biomarker for Alzheimer disease. 3T MR imaging offers a higher contrast and signal-to-noise ratio, yet distortions and intensity uniformity are harder to control. We applied our automated hippocampal segmentation technique to 1.5T and 3T MR imaging data, to determine whether hippocampal atrophy detection was enhanced at 3T.

MATERIALS AND METHODS: We analyzed baseline MR imaging data from 166 subjects from the Alzheimer's Disease Neuroimaging Initiative-1 (37 with Alzheimer disease, 76 with mild cognitive impairment, and 53 healthy controls) scanned at 1.5T and 3T. Using multiple linear regression, we analyzed the effect of clinical diagnosis on hippocampal radial distance, while adjusting for sex. 3D statistical maps were adjusted for multiple comparisons by using permutation-based statistics at a threshold of $P < .01$.

RESULTS: Bilaterally significant radial distance differences in the areas corresponding to the cornu ammonis 1, cornu ammonis 2, and subiculum were detected for Alzheimer disease versus healthy controls and mild cognitive impairment versus healthy controls at 1.5T and more profoundly at 3T. Comparison of Alzheimer disease with mild cognitive impairment did not reveal significant differences at either field strength. Subjects who converted from mild cognitive impairment to Alzheimer disease within 3 years of the baseline scan versus nonconverters showed significant differences in the area corresponding to cornu ammonis 1 of the right hippocampus at 3T but not at 1.5T.

CONCLUSIONS: While hippocampal atrophy patterns in diagnostic comparisons were similar at 1.5T and 3T, 3T showed a superior signal-to-noise ratio and detected atrophy with greater effect size compared with 1.5T.

ABBREVIATIONS: AD = Alzheimer disease; ADNI = Alzheimer's Disease Neuroimaging Initiative; CA = cornu ammonis; CDR = Clinical Dementia Rating; MCI = mild cognitive impairment; MMSE = Mini-Mental State Examination; NC = healthy control

Alzheimer disease (AD), the most common form of dementia in the elderly, is characterized by progressive cognitive and functional decline. AD is increasingly recognized as one of the most important medical problems facing society today. In the United States alone, approximately 5.2 million people have AD. This number is predicted to rise to 13.8 million by 2050.[1] Worldwide, an estimated 35.6 million people lived with dementia in 2010. The worldwide prevalence is expected to reach 65.7 million diagnosed cases in 2030, and 115.4 million, in 2050.[2]

At the tail end of the cognitive spectrum, AD is often preceded by mild cognitive impairment (MCI), an intermediate stage between normal aging and dementia. Patients with MCI show a milder degree of cognitive impairment and preserved ability for day-to-day activities.[3] Patients with MCI are at an increased risk

for developing AD. Identifying patients during this prodromal stage allows early interventions. Noninvasive biomarkers for detecting prodromal AD are greatly needed.[4]

Hippocampal atrophy is the most established structural AD imaging biomarker to date. Hippocampal volume shrinkage is associated with AD-like postmortem hippocampal neuronal loss[5,6] and neurofibrillary tangle deposition.[7] Atrophy of the cornu ammonis (CA) 1 subfield is characteristic of both AD and MCI.[8-11] Greater involvement of CA1 is a risk factor for conversion from MCI to AD.[9,10]

High-resolution MR imaging has helped us visualize subtle anatomic changes in the brain in the initial stages of disease.[12,13] State-of-the-art analytic techniques helped us identify, quantify, and track AD-associated atrophy with great precision. The hippocampus, an area involved early in AD, has been studied via visual rating scales,[14-16] regional volumetric analysis,[10,11,17-19] and shape-deformation methods.[9,20-23] The early studies have used 1.5T, and some of the recent ones have used higher magnetic field strengths. Few studies have compared atrophy detection between 1.5T and 3T field-strength scans.[24-27] One tensor-based morphometry whole-brain study reported that analyses of 1.5T and 3T Alzheimer's Disease Neuroimaging Initiative (ADNI) data from the same subjects did not differ statistically in detecting neurodegenerative changes during 12 months.[26] Hippocampal volumes extracted from the same study cohort at 1.5T and 3T showed only 3.2% test-retest variability.[25] Similar results were reported for manual segmentations in 8 healthy subjects with 1.5T and 3T scans in an epilepsy study.[28]

Using the ADNI-1 dataset, we sought to directly compare 1.5T and 3T segmentations and to determine how well each magnetic field strength detects anatomic differences between subjects who are cognitively healthy (NC) or have MCI and AD as well as between subjects with MCI who converted from MCI to AD in 3 years (MCI converters) and those who did not (MCI nonconverters). Although distortions and intensity uniformity may be more difficult to control at 3T, 3T MR imaging offers higher contrast and signal-to-noise ratio. We hypothesized that higher field MR imaging will offer greater power to detect hippocampal atrophy in the cognitive spectrum from normal aging to AD.

MATERIALS AND METHODS
Subjects
ADNI-1[29-32] is a longitudinal multisite observational study, which started in 2004 and collected cognitive, imaging, and biomarker data from 200 NC subjects, 400 with MCI, and 200 with AD. The goals of ADNI are to determine relationships among clinical, cognitive, imaging, genetic, and biochemical biomarkers as AD evolves from normal aging to MCI to dementia, to discover biomarkers sensitive to early diagnosis, to establish standardized methods for imaging/biomarker collection, and to conduct research on methodologies that could lower the costs of clinical trials.

Our sample consisted of the 187 (22%) of the 842 subjects in ADNI-1 who underwent both 1.5T and 3T MR imaging. 1.5T and 3T brain baseline MR images and their associated clinical data were downloaded from the ADNI public data base (http://adni.loni.usc.edu). The cognitive variables we used to clinically

characterize the research cohorts are the global Clinical Dementia Rating (CDR), sum-of-boxes Clinical Dementia Rating,[33,34] and the Mini-Mental State Examination (MMSE).[35,36] These are the 3 most commonly used global scales to gauge disease severity. The global CDR reflects the overall severity of dementia in which global CDR scores of 0, 0.5, 1, 2, and 3, indicate no cognitive decline, questionable cognitive decline, and very mild, mild, moderate, or severe dementia, respectively. The sum-of-boxes Clinical Dementia Rating ranges from 0 to 18 and reflects clinical deterioration in memory, orientation, judgment and problem solving, community affairs, home and hobbies, and personal care. The MMSE is a 30-point global cognitive screening instrument that evaluates orientation, registration, attention, calculation, recall, and language. All patients with AD met the National Institute of Neurological Disorders and Stroke/Alzheimer's Disease and Related Disorders Association criteria for probable AD.[37] Subjects with MCI met the criteria of Petersen et al for MCI.[3] Our MCI converter-versus-nonconverter analyses included only subjects with follow-up data for 36 months after baseline (36 were MCI converters, and 31 were MCI nonconverters).

Imaging Data Collection, Image Preprocessing, and Analysis
We acquired 1.5T and 3T scans analyzed in this study from 31 ADNI-1 sites on scanners from 3 MR imaging vendors (GE Healthcare, Milwaukee, Wisconsin; Philips Healthcare, Best, the Netherlands; or Siemens, Erlangen, Germany) with a standardized protocol developed to evaluate 3D T1-weighted sequences for morphometric analyses (http://adni.loni.usc.edu/methods/documents/mri-protocols/).[31,38] Participants with structural abnormalities such as hemispheric infarctions, white matter ischemic changes, and focal lesions were excluded from participation.[31] Of the 187 subjects who were imaged at both 1.5T and 3T, 111 (59%) subjects were scanned on GE Healthcare, 24 (13%) on a Phillips Healthcare, and 52 (28%) on Siemens 1.5T scanners. At 3T, 29 (15%) subjects were scanned on GE Healthcare, 50 (27%) were scanned on Phillips Healthcare, and 108 (58%), on Siemens scanners.

The 1.5T and 3T scanning protocols used a 3D sagittal volumetric sequence. The typical 1.5T acquisition parameters were TR = 2400 ms, minimum full TE, TI = 1000 ms, flip angle = 8°, FOV = 24 cm, with a 256 × 256 × 170 acquisition matrix in the x-, y-, and z-dimensions, yielding a voxel size of 1.25 × 1.25 × 1.2 mm³. For 3T scans, the typical parameters were a TR = 2300 ms, minimum full TE, TI = 900 ms, flip angle = 8°, FOV = 26 cm, with a 256 × 256 × 170 acquisition matrix in the x-, y-, and z-dimensions, yielding a voxel size of 1.0 × 1.0 × 1.2 mm³. The 3T protocol included an increased receiver bandwidth to compensate for the increase in chemical shift and susceptibility artifacts.[31] For a detailed description of the acquisition parameters for the various scanner manufacturers, please see Jack et al (2008).[31]

The ADNI MR imaging core at the Mayo Clinic preprocessed the data by using Gradwarp (GE Healthcare) for correction of geometric distortion due to gradient nonlinearity,[39] "B1-correction" for adjusting image intensity inhomogeneity,[31] "N3" bias field correction for reducing residual intensity inhomogeneity,[40] and geometric scaling for adjusting scanner- and session-specific

calibration errors.[31] The raw and preprocessed data are stored at the Laboratory of Neuroimaging at the University of Southern California and are available to the general scientific community for download (http://adni.loni.usc.edu).

MR images were automatically registered by using a 9-parameter transformation to the ICBM53 template.[41] The images were resampled in an isotropic space of 220 voxels along x-, y- and z-axes with a final voxel size of 1 mm^3.

For each field strength, a minimal deformation target was constructed from 9-parameter linearly aligned scans.[42] The minimal deformation target is an unbiased average template image created to represent common features for a group of subjects. This helps to reduce bias by using a template that deviates least from the anatomy of the subjects and to improve statistical power by using a customized template. For this study, 1.5T and 3T baseline scans were nonlinearly aligned to the minimal deformation target developed from 1.5T and 3T images of the NC group.

Two experienced raters manually traced the hippocampal formations of 21 randomly selected subjects (7 NCs, 7 with MCI, and 7 with AD) at 1.5T and 3T by using our in-house hippocampal tracing protocol[43] (intrarater reliability, Cronbach $\alpha = 0.97$; interrater reliability, Cronbach $\alpha = 0.9$). Traces included the hippocampus proper, dentate gyrus, and subiculum as previously described.[44] Tracers were blinded to subject demographics, diagnosis, and the study objective. Anatomic landmarks were followed in all 3 orthogonal viewing planes by using interactive segmentation software. The hippocampi were traced on contiguous coronal sections following a detailed well-established protocol with high intra- and interrater reliability.[45] When boundaries were ambiguous, standard neuroanatomic atlases were consulted.[46,47] Traces included the whole hippocampal head, body, and tail.

Hippocampal segmentation used AdaBoost, our automated machine-learning hippocampal segmentation algorithm, based on a statistical method called "Adaptive Boosting."[48] The technique has been previously described in detail in several publications.[49,50] Briefly, AdaBoost uses a training set (ie, a small number of representative images) to develop classification rules for hippocampal-versus-nonhippocampal tissue. Our training set for this study consisted of 21 subjects, 7 NCs, 7 with MCI, and 7 with AD, who were scanned at both 1.5T and 3T. AdaBoost analyzes the specific feature information contained in the positive and negative voxels (ie, those belonging and not belonging to the structure of interest) of the training dataset and develops segmentation rules based on the optimal combination of features. AdaBoost uses ~18,000 local features, such as image gradients, local curvature of image interfaces, tissue classification as gray or white matter, and statistical information on the likely stereotaxic position of the hippocampus. In the training phase, the algorithm applies mathematic approaches from the fields of machine learning and computer vision[51] to estimate the optimal weighting of these features in a mathematic formula that computes the probability of any given voxel for being inside the hippocampus. AdaBoost performance has been previously validated and has been found to agree with human raters as well as human raters agree with each other (ie, similar to interrater reliability).[49] After statistical rules for hippocampal segmentation are developed, the algorithm is tested in a training set and then applied to the full sample. All segmentations were visually inspected to make sure they appropriately captured the hippocampal anatomy at the given magnetic field strength.

We used an anatomic mesh modeling method called "hippocampal radial distance"[44] to match equivalent hippocampal surface points, obtained from the AdaBoost hippocampal segmentations, across subjects. To match the digitized points representing the hippocampus surface traces in each brain volume, we made the AdaBoost contours spatially uniform by modeling them as a 3D parametric surface mesh.[44] This procedure allows statistical comparisons in 3D and averaging of hippocampal surface morphology across all individuals belonging to a group. Next, to assess the pattern of regional hippocampal atrophy, a medial core, threading down the center of the hippocampus, was computed for each individual. Radial distance was assessed by measuring the distances from the hippocampal surface points to the medial core of the individual's hippocampal surface model.[44] Change in radial distance with time can, therefore, capture localized atrophy. This methodology assures that all hippocampal surfaces are represented by using the same parametric mesh structure. This allows corresponding surface traces and the associated distance measures to be matched across subjects and/or time and averaged across diagnostic groups. Distance fields indexing local expansions or contractions in hippocampal surface morphology can thus be compared statistically between groups.

An ROI was drawn over the lateral hippocampal surface (ie, the area corresponding to CA1) on the 3D hippocampal radial distance model, and the CA1 mean radial distance was computed for each subject at both 1.5T and 3T.

Statistical Methods

We used ANOVA with post hoc Bonferroni correction for multiple comparisons to examine between-group diagnostic differences in age, education, MMSE, CDR, and sum-of-boxes Clinical Dementia Rating. A χ^2 test was used to determine differences in sex distribution.

The effect of diagnosis on hippocampal radial distance was studied by using linear regression while correcting for demographic variables that showed significant between-group differences. Our 3D statistical maps were adjusted for multiple comparisons by using permutation-based statistics with a threshold of $P < .01$. A Student t test was performed for the direct comparison of 1.5T- and 3T-derived radial distance in each diagnostic group.

The observed CA1 regional differences between MCI converters and nonconverters at 3T but not at 1.5T (see "Results") were further examined by using receiver operating characteristic curves. We studied how well the mean CA1 radial distance (in millimeters) discriminated between MCI converters and nonconverters at 3T and 1.5T. We used the Mann-Whitney Wilcoxon test for independent paired samples to statistically compare the sum of the ranks for the mean CA1 radial distance at 1.5T versus 3T and the DeLong partial area under the curve test to statistically compare the area under the curve of the 2 receiver operating characteristic curves.

Demographic characteristics for the diagnostic-comparisons study

Variable	NC (*n* = 53)[a]	MCI (*n* = 76)[a]	AD (*n* = 37)[a]	P Value
Age (yr)	75.4 ± 4.7 (60–87)	75.2 ± 8.2 (55–88)	74.1 ± 8.7 (57–91)	.671
Education (yr)	16.1 ± 2.8 (7–20)	15.9 ± 3.2 (6–20)	14.6 ± 3.2 (7–20)	.055
Sex, M/F	18:35	47:29	13:24	.002[b]
MMSE	29.3 ± 0.9 (26–30)	26.8 ± 1.9 (23–30)	23.3 ± 2.1 (20–27)	<.0001[b]
CDR global	0 ± 0 (0)	0.50 ± 0 (1)	0.69 ± 0.25 (1)	<.0001[b]
CDR sum of boxes	1.0 ± 0.2 (1–2)	2.8 ± 1.0 (2–6)	5.1 ± 1.5 (3–9)	<.0001[b]
1.5T Left hippocampus (mm³)	3859 ± 436 (2707–4730)	3335 ± 588 (1730–4827)	3242 ± 615 (1573–4302)	<.0001[b]
1.5T Right hippocampus (mm³)	3734 ± 591 (2114–5441)	3254 ± 641 (850–4796)	3110 ± 668 (613–4814)	<.0001[b]
3T Left hippocampus (mm³)	3897 ± 758 (408–5087)	3259 ± 601 (1627–4697)	3123 ± 598 (2013–4437)	<.0001[b]
3T Right hippocampus (mm³)	3981 ± 612 (1468–5158)	3389 ± 638 (1800–5053)	3237 ± 672 (1873–4577)	<.0001[b]

RESULTS

Demographics

Twenty-one 3T MR imaging scans failed the automated hippocampal segmentation process and were excluded from further analyses. Thus, our final sample consisted of 166 subjects in ADNI-1 (53 NCs, 76 with MCI, and 37 with AD). Demographic data are shown in the Table. Differences in sex distribution were found ($P = .002$), with the MCI group having significantly more men than women compared with the NC and AD groups. Sex was included as a covariate in the radial distance multiple regression model. As expected, the NC group had the highest MMSE score (29.3 ± 0.9) compared with MCI (26.8 ± 1.9) and AD groups (23.3 ± 2.1) ($P < .0001$). NC had the lowest CDR global score (0 ± 0), followed by MCI (0.50 ± 0) and AD (0.69 ± 0.25) ($P < .0001$). The sum-of-boxes Clinical Dementia Rating followed a similar trend: NC (1.0 ± 0.2), MCI (2.8 ± 1.0), and AD (5.1 ± 1.5) ($P < .0001$).

Hippocampal Regional Volume Differences

Predictably, NC had the largest hippocampal volumes, and the AD group had the smallest (Table). Mean hippocampal volumes at 1.5T were significantly different among NC, MCI, and AD both on the left and the right (ANOVA, $P < .0001$). Between-group differences after Bonferroni correction for multiple comparisons were significant for NC versus MCI (left and right, $P < .0001$) and NC versus AD (left and right, $P < .0001$), but they were not significant when comparing MCI with AD (left, $P = 1$; right, $P = .77$). 3T-derived left hippocampal volumes showed significant differences among NC, MCI, and AD (ANOVA, $P < .0001$). 3T-derived hippocampal volumes were significantly different between NC and MCI (left and right, $P < .0001$) and NC and AD (left and right, $P < .0001$) but not between MCI versus AD (left, $P = .90$; right, $P = .71$).

We used a paired-samples *t* test to directly compare 1.5T versus 3T hippocampal volumes. In the pooled sample, we observed significantly larger right ($P = .03$) but not left ($P = .50$) hippocampal volumes at 3T compared with 1.5T. The intraclass correlation coefficient between 1.5T and 3T volumes was 0.89, and the absolute mean volumetric difference was 1.8%. Within diagnostic groups, significant volumetric differences were seen in the NC group on the right (right, $P = .04$; left, $P = .43$) but not in the MCI (right, $P = .20$; left, $P = .43$) or AD groups (right, $P = .42$; left, $P = .40$).

Surface-Mapping Atrophy Patterns

Bilaterally significant atrophy in the CA1, CA2, and subiculum regions was detected for AD versus NC at both field strengths but was more extensive at 3T (1.5T: left $P_{\text{corrected}} = .0015$, right $P_{\text{corrected}} = .0015$; 3T: left $P_{\text{corrected}} = .0001$, right $P_{\text{corrected}} = .0001$; Fig 1). The pattern of atrophy seen in MCI compared with NC was similar and was similarly more extensive at 3T (1.5T: left $P_{\text{corrected}} = .0019$, right $P_{\text{corrected}} = .0020$; 3T: left $P_{\text{corrected}} = .0008$, right $P_{\text{corrected}} = .0001$). No significant differences in radial distance between AD and MCI were found (1.5T: left $P_{\text{corrected}} = .49$, right $P_{\text{corrected}} = 1.0$; 3T: left $P_{\text{corrected}} = .31$, right $P_{\text{corrected}} = .65$).

The hippocampal radial distance of MCI converters versus MCI nonconverters was not significantly different at 1.5T (left $P_{\text{corrected}} = .80$, right $P_{\text{corrected}} = .74$), yet at 3T, we observed differences in the CA1 radial distance that were significant on the right (right $P_{\text{corrected}} = .01$) and trend-significant on the left (left $P_{\text{corrected}} = .06$, Fig 2). Mann-Whitney Wilcoxon comparison of mean CA1 radial distance between MCI converters and nonconverters showed significant differences at 3T ($P = .003$) and trend-significance at 1.5T ($P = .098$).

The receiver operating characteristic analyses examining the ability of mean CA1 radial distance to discriminate MCI converters and nonconverters resulted in an area under the curve of 0.62 at 1.5T and 0.71 at 3T (Fig 3). While the absolute difference in the area under the curve between the 2 field strengths (Δ area under the curve = 0.09) was relatively large, it was not statistically significant (DeLong test, $Z = 1.5361$, $P = .125$).

DISCUSSION

The bilateral atrophy in the CA1, CA2, and subiculum regions for NC versus AD and NC versus MCI in this present study agrees with findings in prior studies.[9-11,20,52-54] At 3T, MCI converters versus nonconverters presented significant hippocampal atrophy along the lateral and medial edges of the hippocampus corresponding to the CA1 and subicular regions—in concurrence with prior reports by our group based on independent samples.[10]

To date, several groups have compared the performance of 1.5T with 3T for detecting brain atrophy. In a strictly signal-to-noise comparison study, Fushimi et al[24] reported no significant differences in signal-to-noise ratios between 1.5T and 3T in multisection images with a 0-mm gap. Applying tensor brain morphometry and Structural Image Evaluation Using Normalization

of Atrophy algorithms to ADNI-1 1.5T and 3T data, Ho et al[26] reported no significant advantage of 3T over 1.5T for detecting 1-year whole-brain atrophy rates. Perhaps most importantly, 2 groups compared the performance of their automated multiatlas

hippocampal segmentation techniques at 1.5T and 3T in small samples derived from ADNI-1. Lötjönen et al[25] used a sample consisting of 10 NCs, 10 subjects with MCI, and 10 subjects with AD and reported an intraclass correlation coefficient of 0.98 and

Mean CA1 Radial Distance

an absolute volumetric difference between 1.5T and 3T of 3.2%. Macdonald et al,[27] by using 18 subjects with AD and 18 NCs from ADNI-1, reported an intraclass correlation coefficient of 0.97 between 1.5T and 3T hippocampi segmented with their hippocampal multiatlas propagation and segmentation algorithm. Here by using 166 subjects with ADNI-1 imaged at 1.5T and 3T, we report an intraclass correlation coefficient of 0.89 and a mean volumetric difference between 1.5T and 3T measurements across the sample of 1.8%. In addition, here we reveal that 3T seems to show an advantage in detecting subtle region-specific morphometric changes over 1.5T.

The strengths of this study include the large sample size from many ADNI sites across the country, standardized MR imaging protocol, systematic postacquisition analysis, and quality control of phantom-based monitoring of all scanners. Some limitations resulted from the susceptibility-induced geometric distortion and signal losses, which could increase noise, especially in the temporal lobe regions at 3T. Additionally, higher field-strength imaging is more susceptible to chemical shift artifacts.[55,56] Despite these limitations, 3T proved superior to 1.5T for shape analysis and between-group comparisons.

For this study, we had access to only 1.5T and 3T data. It is possible that even higher magnetic field[57,58] strengths such as 7T or 11T may reveal finer scale features and provide superior power for detecting between-group differences. The future directions of this study include conducting longitudinal analyses to show the progressive atrophy that occurs with the disease with time.

CONCLUSIONS

Our 1.5T and 3T hippocampal volumes obtained after automated segmentation with the AdaBoost algorithm were not significantly different between MCI and AD but were significant in NC versus MCI and NC versus AD, with the 3T segmentations resulting in larger mean hippocampal volumes in the NC group. This difference could potentially be explained by the larger CSF pool around the hippocampal formation in subjects with atrophy, which provides good contrast for hippocampal versus extrahippocampal tissue discriminability even at 1.5T—this provides a comparable segmenta-

tion in MCI and AD but not in NCs who lack large CSF pools surrounding the hippocampus in the temporal horn. Our data suggest that 3T images, with their higher contrast and higher signal-to-noise ratio, may enhance the topographic localization of atrophy.
